The Economic Impacts of a Terrorist Attack on the U.S. Commercial Aviation System

by

Peter Gordon, James E. Moore, II, JiYoung Park and Harry W. Richardson University of Southern California

Los Angeles, CA 90089

I. INTRODUCTION

Excepting the major changes induced in the nation's defense posture, we now know that the economic effects of the September 11, 2001, terrorist attacks were of a relatively short-term nature. This corroborates the idea that short-term impact studies of hypothetical attacks can be useful to policy makers allocating limited resources as they evaluate the benefits (costs avoided) of various defensive measures. Here we consider the short-term economic costs of an attack on the U.S. commercial air system. Much is now known about the post-September 11 performance of the air travel industry: It took some years to recover. But a full accounting of the economic costs has, to our knowledge not been done. Nevertheless, careful analysis of the after effects of the events of September 11 can be used to estimate the economic impacts of another attack.

This paper summarizes our work on estimating the economic impacts of a hypothetical terrorist attack on the U.S. commercial air transport system. Where possible, we use data from the post-September 11 experience. We apply IMPLAN®, a 509-sector input-output model of the U.S. economy for 2001, available from the Minnesota IMPLAN Group, Inc. (MIG). Much of our work (Gordon, Moore, II, and Richardson 2007) has focused on estimating spatially disaggregate economic impacts, but a national model is important in this instance. The state-by-state airline revenue losses are particularly difficult to estimate in light of the geographically dispersed nature of airline carriers and related infrastructure and vendors.

We model a seven-day shut-down of the entire U.S. commercial air transportation system, followed by a two-year period of recovery, using the post-September 11 experience of the system as a basis for our analysis. Our overall loss estimates for the two years range from \$214 billion to \$420 billion. Most of these impacts are post-shut down losses incurred during the recovery period.

II. PREVIOUS STUDIES

We are aware of only two other relevant precursor attempts to model substantial disruption of the commercial U.S. air transport system. Balvanyos and Lave (2005) estimated consumer surplus losses from an air travel shut down and reported that the estimated loss would be as much as \$2 billion per day.

Santos and Haimes (2004) published results from an input-output impact simulation of a 10percent U.S. air transport system shutdown associated with \$12 billion in direct effects. These authors derived input-output multipliers of 1.2 (Type I) and 3.6 (Type II) for the U.S., and used these to estimate a range of total losses from \$14.2 billion to \$43 billion for the year.

III. APPROACH AND ASSUMPTIONS

Our approach differs from the two cited studies in several respects. Most important of these is our treatment of the after effects of the attack. Our assumptions and procedures are listed here. These are deliberately conservative.

- We only estimated demand-induced effects. We assumed no supply-side effects. Freight shipments are thought to be quickly made up. And passengers, for the most part, find and engage in productive activities that substitute for air travel. Business people especially will remain at work and engaged in other tasks.
- For losses following the seven-day-shutdown period, we assumed that air freight transport (20 percent of total air revenues) is not diminished and proceeds normally.
 Passenger travel, on the other hand, takes some time to recover because of psychological aftereffects.
- > There is an initial seven-day shutdown of the entire commercial air system.

There is nothing sacrosanct about the seven-day shutdown assumption. It is, after all, a policy not a technical decision. After 9/11 there was a four-day total shutdown. It is reasonable that the shutdown in this type of attack would be longer because the protection against future attacks would require not only controlling who gets on planes but also a search of the areas surrounding airports and the installation of stronger protective and security services at or near airport perimeters. We assume a single attack on a major airport; we believe that this would shut down the whole system with little difference in impact than if several airports were attacked simultaneously. In any event, the shutdown impact is quite small compared to the two-year losses, so the days of shutdown are not a critical variable in the loss estimates. Finally, because the model is linear, it is easy to adjust the loss estimates for full shutdowns of different lengths. The seven days is our best "guesstimate."

To simulate impacts of the shut-down, we set final demand for IMPLAN sector #391, ("air transportation") to zero. This eliminates all passenger and freight traffic. We did not consider any additional ancillary costs associated with the re-routings that occur as the system is shut down.

To simulate the gradual, post-shutdown return to normal traffic, we gathered data on the monthly air passenger losses (domestic as well as international trips) for the 24 months following September 11, 2001. See Table 1. Based on the Holt-Winters forecasting approach, we then estimated trends for each type of air travel from historical data and used these to project what the monthly passenger volumes would have been had there not been an attack on September 11. The differences between projected and actual were assumed to be the monthly air travel losses See Figure 1.

Next, we estimated air traveler expenses for an average person-trip for domestic as well as international travel. See Table 2. These estimates were derived from data provided by the Travel Industry Association of America (2005).

Final demand losses add up to \$1,231 per domestic person-trip and are distributed over the IMPLAN expenditure sectors as shown (airline tickets, ground transportation, accommodations,

food, gifts and shopping, amusement). Corresponding losses per international person-trip are \$2,325.

Table 3 shows estimates of final demand losses for the three periods (the seven-day shutdown, the remainder of year 1, and all of year 2) for both types of passenger traffic and for the various major expenditure sectors. These are derived by applying the expenditures per passenger to one-half of the predicted trip losses on the assumption that most passengers took round-trips, in which case two boardings are associated with each trip expenditure. IMPLAN's multipliers were applied to these direct effects.

These losses were offset by increases in consumption of telecommunication services, to simulate the substitution of teleconferencing for face-to-face business meetings. The question of whether telecommunications and travel are substitutes or compliments is unresolved. It is reasonable to expect that some telecommunications would be used to substitute for travel in the event of a shutdown of the nation's airports. However, we found no usefully identifiable data on these effects. Instead, we assumed a base case five percent increase in telecommunications final demand in the seven days of the air system shut down, followed by a slow return to preshutdown telecommunications demand over the next twenty-four months. We also provide an upper bound estimate of a 25 percent increase in telecommunications final demand

IV. RESULTS

We also calculated values for both Type I and Type II multipliers. The latter calculation is based on the IMPLAN Social Accounting Matrix (SAM), and incorporates a minor modification of the way that household incomes are assessed relative to the procedure IMPLAN calculates multipliers. Applying these two results make it possible to bracket low-end and high-end impacts.

Type I effects are the direct effects from Table 3 and indirect effects consisting of losses by suppliers and vendors in the associated expenditure sectors. Type II multipliers add the induced effects of reduced spending by households with members employed in any of the directly or indirectly affected industries. Both sets of results are shown in Tables 4-1 and 4-2. The expansion of telecommunications services to compensate for reduced business travel provide offsets in the \$20-100 billion range, depending on the projected increase.

For the seven-day shut-down, we predict system losses ranging from \$12.5 billion to \$21.3 billion, depending on the choice of multipliers. The higher bound approximates Balvanyos and Lave's (2005) cost estimates of \$2 billion per day. Balavanyos and Lave take a different approach to this question, estimating costs in terms of changes in consumer surplus. The principal finding in our analysis is that 95 percent of the total impact of the attack is likely to occur in the post-shut-down period. We estimate that net system losses over the entire two-year period would range from \$214.3 billion to \$420.5 billion. These total loss estimates capture the economic consequences that would follow an attack, but exclude the costs associated with the loss of life and the replacement cost of aircraft that would be incurred as the result of an attack.

V. CONCLUSIONS

The estimated cost of deploying countermeasures to the threat man-portable air defense systems (MANPADS) presents to the U.S. airline fleet range from \$10 billion to \$100 billion, depending on the technology and objectives involved (O'Sullivan, 2005). The initial cost of equipping U.S. commercial fleet of approximately 6,800 aircraft range from \$10 billion to \$20 billion, based on estimates of about \$1 million to \$3 million per plane. However, this is not the principal cost of countermeasures. Some countermeasures deteriorate quickly and ust be replaced frequently. As a result, these systems include extensive logistics, refurbishment, training, and maintenance requirements that might impose additional costs of \$5 billion to \$10 billion per year (USDHS, 2004).

We find large loss estimates associated with a shut-down of U.S. airports, primarily due to the sort of long term reductions in air travel demand observed following the nation-wide airport shut-down prompted by the events of September 11. We expect that this drop in demand would be repeated following a subsequent shut-down, but it might also occur in response to the circumstances that might prompt a shut-down, such as a success MANPADS attack. When compared to the estimated costs of MANPADS countermeasure deployment, it appears that the deployment of countermeasures is justified for a wide range of attack probabilities, such as 0.25 over a five-year period.

Estimating the full costs of a major disruption in any large industry is a challenging task. Where we have needed to make assumptions, our choices have erred on the conservative side. On the other hand, the input-output methodology we use to estimate economic impacts does not accommodate many of the substitutions that economic agents can logically be expected to discover as they have time to investigate which adjustments might be best for them. We believe that our various conservative modeling choices help to counter for this modeling limitation.

1 dois 5. Calculation of I mai Domana Dobbes (and Oams) from Tononst I tracks (withinting

 Notes:
 1.
 The reduction in passengers was calculated by multiplying 7/31 by the monthly passenger volume for August 2001.

 2.
 Losses of during a seven-day interruption in service (1.9178% of one year) estimated based on a reduction in final demand in the IMPLAN air

 transportation sector (#391).

3. We assume final demand for Telecommunications services increases by 5% (Telecommunications_A) and by 25% (Telecommunications_B) during the 7 days shutdown and then decreased linearly, month-to-month, over the next two years.

4. Because all passengers are assumed to board with round-trip tickets, we applied one-half of reported air passenger trips to the cost/trip estimates.
